FOREWORD

This report was prepared by the University of Cincinnati under USAF Contract No. AF 33(616)-6900. This contract was initiated Project No. 7023, "Research on Chemical Synthesis", Task No. 73666, "New Synthetic Methods for Polymers and Fluids." The work was administered under the direction of the Materials Central, Deputy for Advanced Systems Technology, Aeronautical Systems Division, with Lt. Robert J. McHenry acting as project engineer.

This report covers work conducted from January 1960 to January 1961.

ABSTRACT

Slater parameters (F's and G's) were calculated for the elements scandium to bromine and are tabulated. These parameters were used to calculate the energies of a wide variety of valence states of these elements, and of their unipositive ions, and hence valence state ionization potentials are derived. These data are tabulated.

PUBLICATION REVIEW

This report has been reviewed and is approved.

I. INTRODUCTION

The present work, aimed at developing semi-empirical methods for estimating bond energies, is a continuation of work initiated by Jaffe and Doak (1). This work was based on an approximate application of Mulliken's "Magic Formula (2) to estimate carbon-metal bond energies in symmetrical metal alkyls.

The "Magic Formula" is an empirical equation, based on a combination of the essential features of both molecular orbital and valence bond theory, expressing the atomization energy of a compound in terms of a series of terms which can either be estimated theoretically or semiempirically. It has the form

$$D_0 = \sum X_{i,j} - \frac{1}{2} \sum Y_{k1} + \frac{1}{2} \sum K_{mn} - PE + RE$$

where the X; term is the energy resulting from the interaction of bonding electrons and is assumed to be expressed as

$$X_{ij} = A S_{ij} \overline{I}_{ij}/(1 + S_{ij})$$

A is an empirical coefficient, adjusted by Mulliken from work on some selected compounds of first row elements, and has a value of 1.16. The \mathbf{T}_i are the mean valence state ionization potentials of atoms i and $\mathbf{j}_i^{i,j}$ and the $\mathbf{S}_{i,j}$ are overlap integrals.

The Y_{k1} and K_{mn} are electron repulsion energies, which have been neglected in the present work, but the importance of which is now under investigation.

The promotion energy, PE, is defined as the energy required to promote the atoms to their respective valence states. The resonance energy, RE, is intended to account for all resonance terms of the valence bond theory, not included in the other terms.

In the original work (1), a long series of approximations were made. $Y_{k\,1}$ and K_{mn} terms were neglected. In the evaluation of $X_{i\,j}$, normal ionization potentials were used instead of valence state ionization potentials. Only a single hybridization was considered, and promotion energies were neglected. Resonance energies were assumed to involve only ionic resonance energies, and were evaluated from electronegativities of the atoms.

Goldfarb (3) has started an investigation aimed at a removal of some of these drastic assumptions. The present work is intended to continue this process. The most important step which needs to be taken

Manuscript released by authors April 1961 for publication as a WADD Technical Report.

is the calculation of the required promotion energies and valence state ionization potentials for a variety of possible hybrid states of the atoms of concern. Later, investigation of the Y_{k1} and Y_{mn} and of the electronegativities is planned.

The calculation of the needed valence state ionization potentials and promotion energies is based on calculation of the energies of valence states. Two methods are available for such calculations. due to Mulliken (4), is based on Slater's treatment of the complex It involves expression of the valence state energy in terms atom (5). of certain integrals over the radial atomic wave functions F_1^K and G_{1-1}^k , the so-called Slater parameters. The other, proposed by Moffitt (6), expands the energy of valence states directly in terms of energies of spectroscopic (stationary) states of the atom. Slater treatment of the complex atom involved no assumptions, and hence no approximations, the two methods would be equivalent. Unfortunately, however, considerable approximations are involved in the Slater method; the worst of these are probably the neglect of configuration interaction and of spin-orbit coupling, and the assumption of perfect Russell-Saunders coupling. We believe that the Mulliken method, by averaging over more states tends to minimize these approximations. Also, this method appears to lend itself more readily to machine calculation, and hence we have chosen this method. Consequently Slater parameters were needed for all elements of interest. The present report summarizes the parameters obtained, and the valence state promotion energies and ionization potentials computed with their

II. METHODS AND RESULTS

A. Slater Equations for Stationary States.—The Slater parameters may be computed theoretically from the atomic radial wave functions. Such computations, however, are time-consuming. They would either involve finding, in the literature, the wave functions of all the atoms and ions needed, almost necessarily obtained in the same or equivalent approximation, or their calculation. No such data appear to be available in an approximation better than Slater orbitals, which was deemed inadequate for the present purpose. Although a Hartree-Fock calculation could undoubtedly be programmed, it was not deemed desirable to spend the time required to do so and carry out the massive computation involved.

Consequently, a semi-empirical technique was employed which is based on the well-known energies of spectroscopic states (7). In order to make use of these data, expressions for the energies of the spectroscopic states were required. These were obtained using a program written in this laboratory for the IEM 650 MDDPM (3). Since the

methods are well-known, no details will be given.

B. <u>Slater Parameters</u>.-Given the equations for the energies of spectroscopic states in terms of the Slater parameters and empirical energy values, it should be a simple matter to solve for the parameters. However, a number of problems arise.

In the transition elements, generally a large number of spectroscopic states are observed and consequently more equations are available than parameters which need to be evaluated. Since the theory on which the equations are based is approximate, different values would be obtained by different choice of equations. The most logical procedure to follow under these circumstances appears a least squares method, which gives the values of the parameters which best represent all data. Accordingly, the equations were fitted by a standard multiple regression technique, using the IBM 650 MDDPM to carry out the needed computation.

Theory does not require the Slater parameters to be identical for different configurations, since the radial wave-functions generally However, quite frequently, insufficient experimental data are available to find all parameters involved in a single configuration from the states of that configuration alone. Further, the equation for hybrid valence states of a given configuration frequently involves parameters not available from any states of the same configuration. Thus, e.g. in the valence state of carbon involving four tetrahedral hybrids, $(sp^3)^4$ or t_e^4 , F_{ss} terms are required which do not enter into any of the spectroscopic states of the same configuration sp³ of carbon. Accordingly, it was assumed throughout that the parameters could be treated as constants for an element, independent of the configuration, and multiple regression was generally performed on data from all configurations of interest, pooled into one regression. Calculations for single configurations are also reported, and tend to indicate that the overall fit of the equations was not appreciably adversely affected by this procedure, so that it may be concluded that the approximation involved in the assumption of constants F's and G's is less serious than some of the other approximations.

In cases where the number of equations was equal to the number of data, the parameters could, of course, be calculated directly by solution of the simultaneous equations, and this was done. In a few cases, some of the parameters could not be obtained at all, either because of lack of experimental data, or because of the nature of the equations. In such cases the missing parameters were estimated by extrapolation methods, or from theoretical calculations in the literature.

The experimental energies of spectroscopic states were taken from the tabulations of Moore (7). In states of higher multiplicity than one, means were used, weighted according to (2j+1). Where several states of equal L and S (equivalent multiplets) occur in the same configuration, the sum of all of them was used, since the Slater equation program was unable to perform the configuration interaction calculation needed to seperate the states.

Each energy expression involves, aside from the Slater parameters, a term constant for each configuration, W^0 . The W^0 for the lowest (ground state) configuration is treated as the constant term (intercept) of the multiple regression. The W^0 terms of the other configurations were treated as a sum, W^0 of the lowest configuration, and ΔW^0 , the excess above this. The ΔW^0 's were treated as additional parameters in the multiple regression.

The input data for the multiple regression analysis are given in Tables 1-24. In these tables, the first column specifies the configuration, the second the spectroscopic state, the last its energy, and the intervening columns give the energy equation. The results of the multiple regressions are shown in Tables 25-49. The first row gives the degrees of freedom available in the analysis, the second F, the variance ratio, and subsequent rows give the W's, F's and G's. Where available, standard deviations are given. Estimated values are so indicated.

The terms $F_2(dd)$ and $F_4(dd)$ of CuI are calculated by extrapolation of the corresponding parameters of FeI, CoI, and NiI. Values computed for CoI agree well with theoretically calculated ones (8). None of the $F_2(pp)$ terms for Fe, Co, Ni or Cu can be calculated from spectroscopic data. In accord with general practice, they have been neglected throughout.

In the calculation of valence state energies, some WO values for higher configurations are often needed which cannot be calculated from empirical data. Such values have been estimated on the basis of the assumption that promotion of an electron from an x orbital to a y orbital requires the same energy for any configuration, so that the promotion $xy \longrightarrow yy$ requires the same energy as $xx \longrightarrow xy$. Hence,

$$W_{o}(xy) - W_{o}(xx) = W_{o}(yy) - W_{o}(xy)$$

 $W_{o}(xx) - 2W_{o}(xy) + W_{o}(yy) = 0$

so that the unknown parameter $W_o(yy)$ is estimated as $W_o(yy) = 2W_o(xy) - W_o(xx)$

There are frequently different possible ways of making such estimates, which permit the testing of the assumption. Thus, $W_0(d^6p^2)$ of FeI, which is unobtainable empirically since no states of this configuration have been observed, may be estimated by any of the following three independent ways:

$$W_o(d^6p^2) = 2W_o(d^7p) - W_o(d^8) = 82,572.73 \text{ cm}^{-1}$$
 $W_o(d^6p^2) = W_o(d^7p) - W_o(d^6sp) - W_o(d^7s) = 103,155.52 \text{ cm}^{-1}$
 $W_o(d^6p^2) = 2W_o(d^6sp) - W_o(d^6s^2) = 104,899.66 \text{ cm}^{-1}$

Two of these are seen to agree excellently, the third only moderately well. Similarly for $W_o(d^5p^2)$ of FeII: $W_o(d^5p^2) = 2W_o(d^6p) - W_o(d^7) = 178,598.39 \text{ cm}^{-1}$

$$W_{o}(d^{5}p^{2}) = 2W_{o}(d^{6}p) - W_{o}(d^{7}) = 178,598.39 \text{ cm}^{-1}$$

$$= W_{o}(d^{6}p) + W_{o}(d^{5}sp) - W_{o}(d^{6}s) = 198,020.38 + G_{sp} \text{ cm}^{-1}$$

$$= 2W_{o}(d^{5}sp) = W_{o}(d^{5}s^{2}) = 193,668.22 + G_{sp} \text{ cm}^{-1}$$

suggesting $W_0(d^5p^2) = 178,598.39$ cm⁻¹ and $G_{sp} = 17,000$ cm⁻¹. This type of relation was required repeatedly, and is referred to as the \triangle_0 relation.

C. Valence State Equations.-A valence state is defined as the state of an atom in which it exists in the molecule. Such states are not stationary states, and hence not observable, but are purely hypothetical states which can, however, be treated theoretically.

The formation of a valence state may be conceived as follows: Remove all atoms, with their electrons, from a central atom in a molecule, holding at the same time the electrons of the central atom fixed, i.e. at constant angular momentum and spin. In this process there results the valence state, in which the orbital angular momentum of each electron is fixed, while the spin is completely unknown. This lack of knowledge of spin arises because, in the molecule, each electron is paired with an electron from another atom, and removal of these other electrons leaves the electrons of the central atom with indeterminate spin.

The energy of such valence states can be treated exactly analogously to the energy of spectroscopic states (4). A program was written which permitted the generation of the energy of the valence states in terms of the Slater parameters discussed above. This program requires specification of a configuration, including information as to which electrons are to be considered as valence electrons, and of the wave function of any electrons occupying hybrid orbitals. It is capable of handling any configuration made up of any number of s, p and d electrons. In case the electrons not involved in bonding (non-bonding electrons) do not completely fill the available orbitals, the program

makes computations for all possible assignments of d electrons to d orbitals and p electrons to p orbitals (9).

This program has been used to derive the energy equations, in terms of the Slater parameters, for a wide variety of valence states of the elements scandium through bromine. The valence states were specified in terms of the hybrid orbitals involved in the bonds. No complete treatment of all possible hybrids is possible, but it is believed that a sufficient variety of configurations and hybrids was included to permit the recognition of trends. The hybrids chosen were those believed, for each configuration, to be the ones most likely to lead to the formation of stable bonds. For each element, the most commonly observed coordination numbers were chosen, and in addition higher coordination numbers (four) were included. The hybrid orbitals used are summarized in Table 50, where σ , π , π' , δ , δ' refers to the five d orbitals, d₂2, d_{x2}, d_{y2}, d_{xy} and d_x2-y², respectively, and x, y and z refers to the orbitals p_x, p_y and p_z, respectively.

The valence state ionization potential is defined as the energy required to remove an electron from one of the bonding orbitals of the atom in its valence state. Thus, the energy is required of the rather peculiar valence state of the ion with the one valence electron of the free atom missing. The program just described is capable of deriving the equations for such valence states, and was used to obtain the valence states for the ions.

D. Valence State Energies.-Given the valence state equations (cf. Section II C) and the Slater parameters (Section IIB), it is a simple matter of substitution to obtain valence state energies. The only difficulty that arises is that the valence state equation specifies the energy in terms of all the Slater parameters, including F0 1, and G1 1, whereas these quantities, since they occur equally in every spectroscopic state of a given configuration, cannot be evaluated empirically, but are included in the W terms. However, in a valence state of a given configuration, they occur in a different manner. Thus, since each of the orbitals of the (sp³)4 (te⁴) state of carbon, e.g., involves a contribution from the sorbital, F6s appears in the valence state equation, together with F5p and F6p. In the spectroscopic states of sp³ carbon, however, only one electron is in the sorbital, and hence F6s does not occur. Consequently it is necessary to eliminate the F6s before the substitution can be performed. This is always possible by taking an appropriate combination of W6s, three, W6(pⁿ), W6(pⁿ⁻¹s), and W6(pⁿ⁻²s²), in the case of s and p electrons only, and six W6(dⁿ), W6(dⁿ⁻¹s), W6dⁿ⁻¹p, W6dⁿ⁻²s², W6(dⁿ⁻²sp), and W6(dⁿ⁻²p²) in the case of s,p, and delectrons. Also, in the case of more than half-filled shells, the spectroscopic states are calculated on the basis of complementary configurations, i.e. configurations in which vacancies are treated like electrons,

electrons like vacancies. This treatment also requires adjustment of W^{\bullet} 's. These eliminations, adjustments, and the subsequent substitution are not difficult. However, since the calculations were desired for several hundred valence states, a program for the IBM 650 MDDPM was written to perform all these functions. This program uses as input the output from the valence state equation program, and the data from the multiple regression, i.e. the Slater parameters, and finally produces the valence state energies.

It was not felt necessary to calculate the valence state ionization potentials for all possible valence states of any given configuration and hybrid type. Among the many possible states of a given configuration the one with the lowest promotion energy was chosen. was invariably one of highest multiplicity, in accord with Hund's rule. Within a given multiplicity, energy differences were, in general, quite small, and it is believed that no significant differences exist. Calculations for the ion were then restricted to the particular valence state chosen, and results are given only for these states. results are shown in Tables 51-60.

Finally, valence state ionization potentials are calculated by adding the normal ionization potential, obtained from Moore's tables (8) and the promotion energy of the ion, and subtracting the promotion energy of the atom.

III. DISCUSSION

The data presented in the accompanying Tables should prove useful for many calculations. In particular, they will be used for substitution into the Mulliken magic formula, both in the X terms and as promotion energies PE. In addition, they will be used, when supplemented by electron affinities now being computed, in the calculation of electronegativities for dements in various hybrid states. In addition, calculation of Y_{k1} and K_{mn} integrals, now under investigation, will provide all terms needed for an application of the magic formula.

^{*} Terms estimated using ΔW_0 relationship.

@Note:

The variance ratio F is the ratio of the estimated of variance for the improvement due to regression to the estimate of the vari-

ance of the regression itself. Thus F measures the goodness of fit and is to be compared with a critical F taken from standard tables.

The degree of freedom is expressed, in Tables 31-54, as D.F. with the number of independent variables n in the numerator and the number of degrees of freedom (= N - n-1, where n is the number of data used) in the denominator.

^{+*} Terms calculated by hand.

MEMORANDUM FOR AFRL/RXOP
ATTN: Robin Hayes

FROM: AFRL/RXAS

SUBJECT: Technical reports WADD-TR-61-84-PT-1 and WADD-TR-61-84-PT-2

I have read through both technical reports you sent me - reference WADD-TR-61-84-PT-1 (U) Empirical Methods for Calculation of Bond Energies. Part 1 dated May 1961 and WADD-TR-61-84-PT-2 (U) Empirical Methods for Calculation of Bond Energies. Part 2 dated Sep 1963. In both cases the computations that were done, while significant in the early 1960s, could be reproduced now with better accuracy by modern computational methods and equipment in a matter of a few hours. Thus the data presented in the reports is of historical value only. Since I saw no discussions of specific strategic materials or weapon systems, I conclude that both reports should be assigned a distribution statement A. If you have any further questions, please feel free to contact me by e-mail at alan.yeates@us.af.mil or by phone at 312-785-9138 or (937)255-9138 (comm).
